Abstract

High-precision photometry of solar-like members of the open cluster M67 with *Kepler/K2* data has recently revealed enhanced activity for stars with a large Rossby number, which is the ratio of rotation period to the convective turnover time. Contrary to the well established behavior for shorter rotation periods and smaller Rossby numbers, the chromospheric activity of the more slowly rotating stars of M67 was found to increase with increasing Rossby number. Such behavior has never been reported before, although it was theoretically predicted to emerge as a consequence of antisolar differential rotation (DR) for stars with Rossby numbers larger than that of the Sun, because in those models the absolute value of the DR was found to exceed that for solar-like DR. Using gyrochronological relations and an approximate age of 4 Gyr for the members of M67, we compare with computed rotation rates using just the $B - V$ color. The resulting rotation–activity relation is found to be compatible with that obtained by employing the measured rotation rate. This provides additional support for the unconventional enhancement of activity at comparatively low rotation rates and the possible presence of antisolar differential rotation.

Key words: dynamo – stars: activity – stars: late-type – stars: magnetic field – starspots

1. Introduction

Main-sequence stars with outer convection zones have long displayed a remarkable universality regarding their dependence of normalized chromospheric activity on their normalized rotation rate. This dependence is evident over a broad range of activity indicators including X-ray, $H\alpha$, and, in particular, the normalized chromospheric Ca II H+K line emission, R'_{HK} (e.g., Noyes et al. 1984; Vilhu 1984). To compare late-type stars of different spectral types, these and other investigators since then normalized the rotation period P_{rot} by the star’s convective turnover time τ , as determined from conventional mixing length theory. This step is obviously model-dependent, but different prescriptions for τ as a function of $B - V$ all have in common that τ increases monotonically with $B - V$. With this normalization, the rotation–activity relations of stars of different spectral type collapse onto a universal curve. Empirically, the most useful prescription for the function τ ($B - V$) is one that minimizes the scatter of R'_{HK} as a function of τ/P_{rot} , i.e., the inverse Rossby number.

For $\tau/P_{\text{rot}} \ll 1$ (slow rotation), the activity indicator R'_{HK} increases approximately linearly with τ/P_{rot} , but saturates for $\tau/P_{\text{rot}} \gg 1$. In this Letter, we focus on a new behavior for values of τ/P_{rot} that are smaller than what was usually considered in earlier investigations. In this regime, Giampapa et al. (2017) found that R'_{HK} increases with decreasing values of τ/P_{rot} . The same trend is reproduced when using the earlier R'_{HK} values of Giampapa et al. (2006) at somewhat higher spectral resolution, where the effects of color-dependent contamination from the line wings is smaller. Also calibration uncertainties were shown to be small.

The unconventional scaling of R'_{HK} with τ/P_{rot} can be associated with a theoretically predicted increase in differential rotation (DR) at Rossby numbers somewhat above the solar value, i.e., for slower rotation in the normalized sense. This is

the regime of antisolar DR (slow equator, fast poles). The associated increase of magnetic energy with decreasing rotation rate was first noticed by Karak et al. (2015); see their Figure 12(b). The sign reversal of DR, however, has a much longer history and goes back to early work by Gilman (1977). More recently, with the advent of realistic high-resolution simulations of solar/stellar dynamos, it became evident that dynamo cycles could only be obtained at rotation rates that are about three times faster than that of the Sun (Brown et al. 2011). Later, Gastine et al. (2014) found hysteresis behavior in the transition from solar-like to antisolar-like DR as a function of stellar rotation rate. Solar-like DR could then be obtained for initial conditions with rapid rotation. This led Käpylä et al. (2014) to speculate that the Sun might have inherited its solar-like DR with equatorward acceleration and slow poles from its youth when it was rotating more rapidly. However, subsequent models with dynamo-generated magnetic fields by Fan & Fang (2014) did not confirm the existence of hysteresis behavior. Thus, at the solar rotation rate, simulations do indeed produce antisolar DR. This is a problem of all solar dynamo simulations to date, but it may be hoped that the qualitative trends found by Karak et al. (2015) would still hold for the Sun, but at slightly rescaled rotation rates.

The present work supports the prediction by Karak et al. (2015) of a reversed trend in the rotation–activity diagram at very low values of τ/P_{rot} . The purpose of this Letter is to compare the new data of Giampapa et al. (2017) with those of other stars, notably those of the Mount Wilson HK project (Baliunas et al. 1995).⁶ We focus here particularly on the main-sequence stars of Brandenburg et al. (2017; hereafter **BMM**) and Saar & Brandenburg (1999; hereafter **SB**), for which cyclic dynamo properties have been analyzed in detail. Many of those stars have two cycle periods, which fall into one of two classes in diagrams showing the

Note. T_{eff} is in kelvins, τ and P_{rot} are in days, and age is in gigayears. P_{rot}^* (in days) is computed from Equation (2) assuming an age of $t = 4$ Gyr,

rotation-to-cycle-period-ratio versus R'_{HK} or age. These properties give us a perspective on the stars' evolutionary state in a broader context. For the stars of the *Kepler* sample of Giampapa et al. (2017), the time series are still too short, so no information about cyclic activity exists as yet. However, based on earlier simulations, we suggest that those stars can exhibit chaotic variability in R'_{HK} by up to 0.35 dex that might be detectable over longer time spans.

2. Representation of the Data

To be able to discuss individual stars in their rotation–activity diagrams, we denote the stars of M67 by uppercase roman and lowercase Greek characters and identify them by their Sanders number *S* in Table 1. The F and G dwarfs of BMM, represented by lowercase italic characters, their K dwarfs, indicated by lowercase roman characters, and the four stars of SB with $P_{\text{rot}}/\tau \geq 2.4$, indicated by the numbers 1–4, are identified by their HD or KIC numbers in Table 2. In addition to $B - V$, P_{rot} , and R'_{HK} , we also give in both tables the effective temperature T_{eff} and, for $B - V > 0.495$, the gyrochronological age t from

Table 2

the relations of Mamajek & Hillenbrand (2008),

$$t = \{P_{\text{rot}}/[0.407(B - V - 0.495)^{0.325}]\}^{1.767}; \quad (1)$$

see also Equation (9) of BMM.⁷ Equation (1) can be inverted to compute instead P_{rot} under the reasonable assumption that $t = 4$ Gyr is valid for all stars of M67; evidence comes from isochrones (Sarajedini et al. 2009; Önehag et al. 2011), gyrochronology (Barnes et al. 2016), and chromospheric activity combined with gyrochronology (Giampapa et al. 2017). This yields

$$P_{\text{rot}}^* = 0.407(B - V - 0.495)^{0.325} t^{0.565}, \quad (2)$$

where the asterisk is used to distinguish the computed value from the measured one. Next, using the semi-empirical relationship for $\tau(B - V)$ of Noyes et al. (1984) in the form

$$\log \tau = 1.362 - 0.166x + 0.03x^2 - 5.3x^3, \quad (3)$$

⁷ This relation gives 3%–14% smaller ages than the one of Barnes (2010), which was also used by Giampapa et al. (2017), taking τ from Barnes & Kim (2010). Here we use Equation (1) for consistency with BMM.

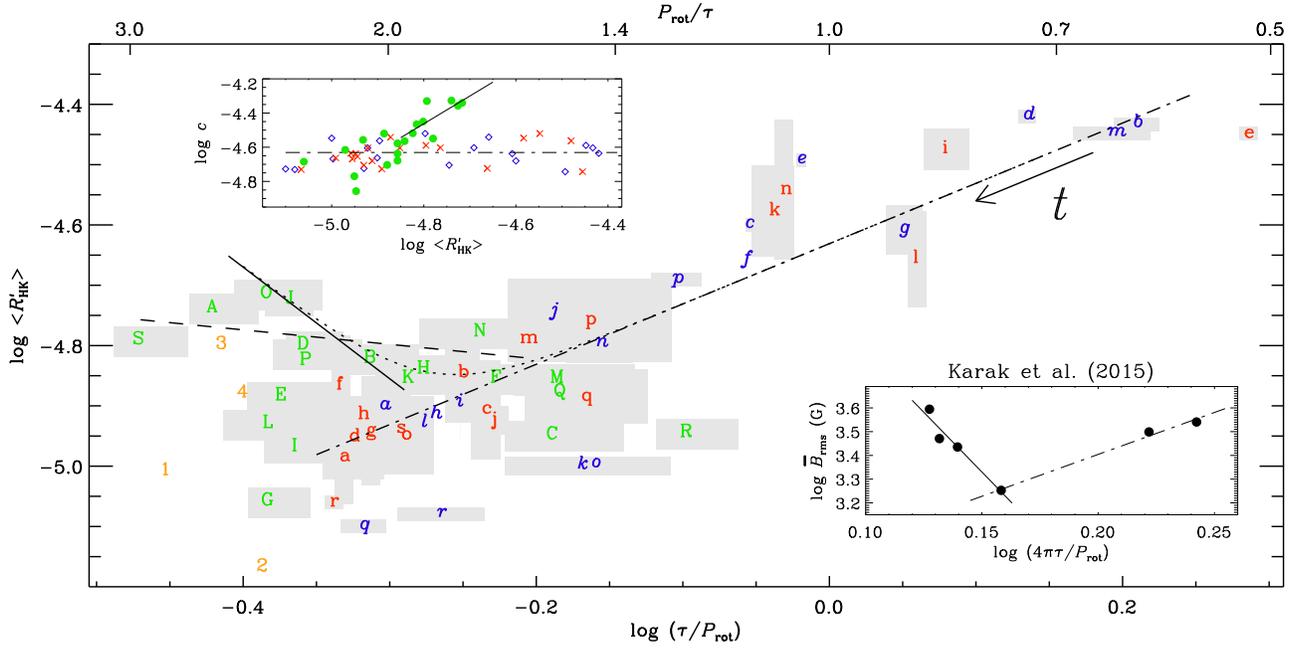

Figure 1. $\log\langle R'_{\text{HK}} \rangle$ vs. $\log(\tau/P_{\text{rot}})$ for the stars of M67 with known rotation periods as green uppercase letters, the F and G dwarfs of BMM as blue italics characters, the K dwarfs of BMM as red roman characters, and the four stars of SB with $P_{\text{rot}}/\tau \geq 2.4$ as orange numbers 1–4. On the upper abscissa, the Rossby number P_{rot}/τ is given. The dashed–dotted line shows the fit of BMM, whereas the solid line represents a fit to the residuals in Equation (5) for the nine stars with $\log\langle R'_{\text{HK}} \rangle \geq -4.85$. The dashed line is a direct fit to the same nine stars and the dotted line shows the fit given by Equation (6). The arrow indicates the anticipated evolution with increasing age t . Some of the symbols have been shifted slightly to avoid overlap. The Sun corresponds to the blue italics *a*. The upper inset shows the residual $\log c$ vs. $\log\langle R'_{\text{HK}} \rangle$ for the stars of M67 as green filled circles, the F and G dwarfs of BMM as blue diamonds, and the K dwarfs of BMM as red crosses. The lower inset shows the increasing magnetic field strength for small values of $4\pi\tau/P_{\text{rot}}$ from Figure 12(b) of Karak et al. (2015).

with $x = 1 - (B - V)$ and for $B - V < 1$, we obtain τ/P_{rot}^* as a monotonically increasing function of $B - V$ in the range from 0.55 to 0.8.

Given these relations, we first show in Figure 1 all stars with measured rotation periods in the rotation–activity diagram. Error bars in $\langle R'_{\text{HK}} \rangle$ and P_{rot} are marked by gray boxes. The stars of BMM follow an approximately linear increase that can be described by the fit $\log\langle R'_{\text{HK}} \rangle \approx \log(\tau/P_{\text{rot}}) + \log c$, where $\log c \approx -4.63$. However, in spite of significant scatter, there is a clear increase in activity for most of the stars of the sample of M67 as τ/P_{rot} decreases. HD 187013 and 224930 (orange symbols 3 and 4 with $P_{\text{rot}}/\tau = 2.6$ and 2.5, respectively) of the Mount Wilson stars are found to be compatible with this trend. We show two separate fits in Figure 1, a direct one and one that has been computed from a fit to the residual between $\log\langle R'_{\text{HK}} \rangle$ and $\log(\tau/P_{\text{rot}})$, i.e.,

$$\log\langle R'_{\text{HK}} \rangle - \log(\tau/P_{\text{rot}}) = \log c_1 + \rho \log\langle R'_{\text{HK}} \rangle. \quad (4)$$

In the upper inset of Figure 1, we denote this residual by $\log c$, where c is a function of $\langle R'_{\text{HK}} \rangle$. Equation (4) is then written in terms of an expression for $\log\langle R'_{\text{HK}} \rangle$ versus $\log(\tau/P_{\text{rot}})$. The parameters in Equation (4) have been computed based on the nine stars for which $\log\langle R'_{\text{HK}} \rangle \geq -4.85$. This yields $\log c_1 \approx 2.92$ and $\rho \approx 1.54$, which is shown in the upper inset of Figure 1 as a solid line.⁸ Solving for $\log\langle R'_{\text{HK}} \rangle$ gives

$$\log\langle R'_{\text{HK}} \rangle = \log c_2 + \mu_2 \log(\tau/P_{\text{rot}}), \quad (5)$$

where $\log c_2 = \mu_2 \log c_1 \approx -5.41$ with $\mu_2 = (1 - \rho)^{-1} \approx -1.85$. It is shown in the main part of Figure 1 as a solid line. By comparison, the direct fit for the same nine stars gives $\log c_2^* \approx -4.87$ and $\mu_2^* = -0.24$ and is shown in Figure 1 as a dashed line. In addition, we combine the fit of BMM with that of Equation (5) as

$$\langle R'_{\text{HK}} \rangle = \{ [c_0(\tau/P_{\text{rot}})]^q + [c_2(\tau/P_{\text{rot}})^{\mu_2}]^q \}^{1/q}, \quad (6)$$

where $c_0 = 10^{-4.631}$ is the residual of BMM and $q = 5$ is chosen large enough to make the transition between the two fits sufficiently sharp. This special representation now applies to the whole range of τ/P_{rot} , and we return to it in Section 3. To remind the reader of Figure 12(b) of Karak et al. (2015), we show in the lower inset of Figure 1 the magnetic field strength versus $4\pi\tau/P_{\text{rot}}$. The 4π factor emerges because in those models, rotation is controlled by the Coriolis force, which is proportional to 2Ω , where $\Omega = 2\pi/P_{\text{rot}}$ is the angular velocity.

Next, we compare with the diagram, where τ/P_{rot}^* is estimated just from $B - V$ using gyrochronology; see Equation (2) and Figure 2. Now, the direct fit for the 15 stars with $\log\langle R'_{\text{HK}} \rangle \geq -4.85$ gives $\log c_2^{\text{dir}} \approx -5.12$ and $\mu_2^{\text{dir}} = -0.87$ and is shown as a dashed line. The inset reveals that τ/P_{rot}^* is indeed a monotonically increasing function of $B - V$ in the range from 0.55 to 0.8, as asserted earlier in this section. The data points for the stars of M67 scatter around this line. The corresponding relation obtained using the gyrochronology relation of Barnes (2010) is also given. The difference of about 0.3 dex results from the fact that the $\tau(B - V)$ of Barnes & Kim (2010) is nearly twice as large as that of Noyes et al. (1984).

⁸ Giampapa et al. (2017) computed $\log c_1$ and ρ for all 19 stars using $\tau(B - V)$ from Barnes & Kim (2010) instead of Noyes et al. (1984); their values are therefore somewhat different: $\log c_1 \approx 1.11$ and $\rho \approx 1.25$.

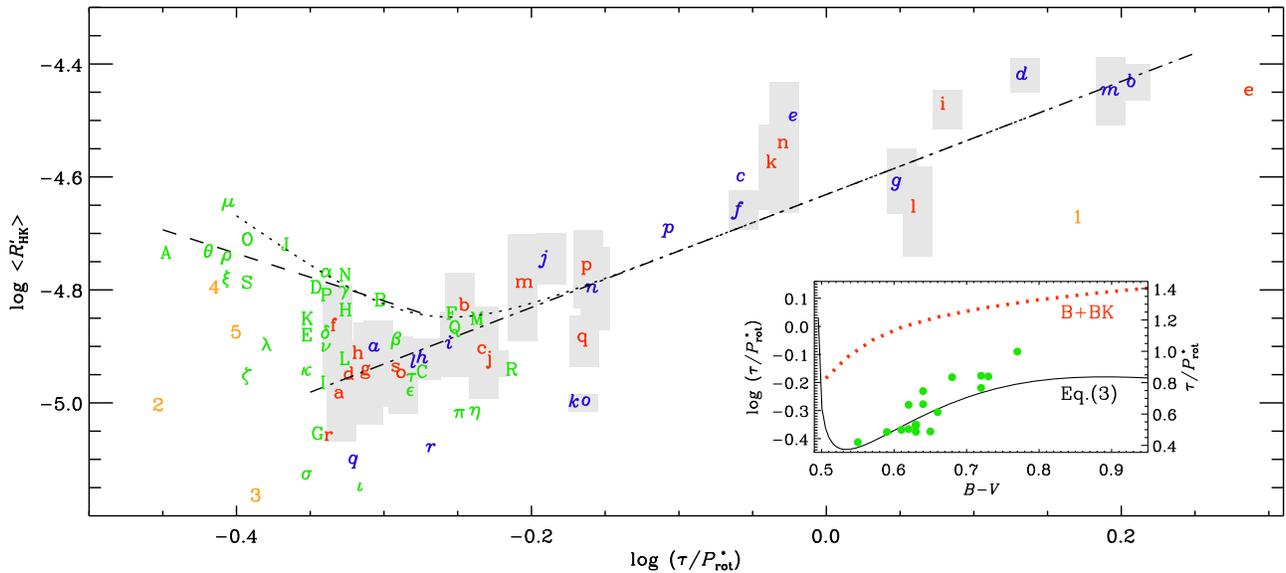

Figure 2. Similar to Figure 1, but now with rotation periods computed from $B - V$ using Equation (2) and the assumption that M67 is 4 Gyr old. (The green symbols would end up further to the left if we assumed instead an age of 5 Gyr.) Here all stars are included—not just those for which P_{rot} would also be available; see Table 1. The inset shows τ/P_{rot}^* as a function of $B - V$ using Equation (3). The data points for the stars of M67 are overplotted to illustrate the scatter and the range in $B - V$ covered by the data. The red dotted line without surrounding data points shows the result using the gyrochronology relation of Barnes (2010) and Barnes & Kim (2010) for $\tau(B - V)$, denoted by B+BK.

As a function of τ/P_{rot}^* , the reversed trend of $\log \langle R'_{\text{HK}} \rangle$ is even more pronounced. S1420 (green S) appears now to be more rapidly rotating: $P_{\text{rot}}^* = 20.7$ days, whereas $P_{\text{rot}} = 24.8$ days; see Table 1. Another example is S1106 (green L), where $P_{\text{rot}}^* = 24.3$ days whereas $P_{\text{rot}} = 28.4$ days. On the other hand, S801 (green C), S1218 (green N), and S1307 (green R) are now predicted to rotate slower than what is measured. To understand these departures, we need to remind ourselves of the possibility of measurement errors, notably in P_{rot} , variability of $\langle R'_{\text{HK}} \rangle$ associated with cyclic changes in their magnetic field, and of the intrinsically chaotic nature of stellar activity. Also, of course, the gyrochronology relation itself is only an approximation to empirical findings and not a physical law of nature.

3. Evolution and Relation to Reduced Braking

Following van Saders et al. (2016) and Metcalfe & van Saders (2017), we would expect that evolved stars lose their large-scale magnetic field and thereby undergo reduced magnetic braking. Their angular velocity should then stay approximately constant until accelerated expansion occurs at the end of their main-sequence life. For those stars, it might be difficult or even impossible to ever enter the regime of antisolar DR. This could be the case for α Cen A (HD 128620, blue *k*), KIC 8006161 (blue *o*), and 16 Cyg A and B (HD 186408 and 186427, i.e., blue *q* and *r* symbols, respectively). These are stars that rotate faster than expected based on their extremely low chromospheric activity. Given the intrinsic variability of stellar magnetic fields, it is conceivable that the idea of reduced braking may not apply to all stars. Others would brake sufficiently to enter the regime of antisolar rotation and then exhibit enhanced activity, as discussed above. With increasing age, those stars would

continue to slow down further and increase their chromospheric activity, as seen in Figure 2.

In principle, it is possible that stars exhibit a systematic dependence of the residual

$$\log \tilde{c} = \log \langle R'_{\text{HK}} \rangle - \log [\text{“rhs of Equation (6)”}] \quad (7)$$

on effective temperature. This is examined in Figure 3. It turns out that this residual is essentially flat, i.e., there is no systematic dependence on T_{eff} , and it is consistent with random departures which do, however, become stronger toward larger T_{eff} , as indicated by the gray boxes in Figure 3.

The work of Karak et al. (2015) has demonstrated that in the antisolar regime, the magnetic activity can indeed be chaotic and intermittent. Thus, depending on chance, a star in this regime may appear particularly active (e.g., S1252, green O symbol with $\log \langle R'_{\text{HK}} \rangle = -4.72$), while others could be particularly inactive (e.g., S969, green G symbol, with $\log \langle R'_{\text{HK}} \rangle = -5.06$). Other examples are S1449 (green σ with $\log \langle R'_{\text{HK}} \rangle = -5.13$) and S1048 (green ι with $\log \langle R'_{\text{HK}} \rangle = -5.17$). We must therefore expect that the magnetic activity of some of these stars could still change significantly later in time, perhaps on decadal or multi-decadal timescales. In fact, we note from a comparison of the Ca II measurements in Giampapa et al. (2017) with those from the initial chromospheric activity survey of over a decade ago (Giampapa et al. 2006) that the R'_{HK} values for the specific stars mentioned above, S969 and S1048, are now each lower by about 20%, while that for S1449 is lower by 23%.

Given that the more massive stars of M67 are on their way to becoming subgiants (e.g., Motta et al. 2016), we now discuss whether this could explain their enhanced activity. Properties important for convection such as luminosity and radius may increase substantially above the main-sequence values before reaching the turnoff. To compare with observations, it is convenient

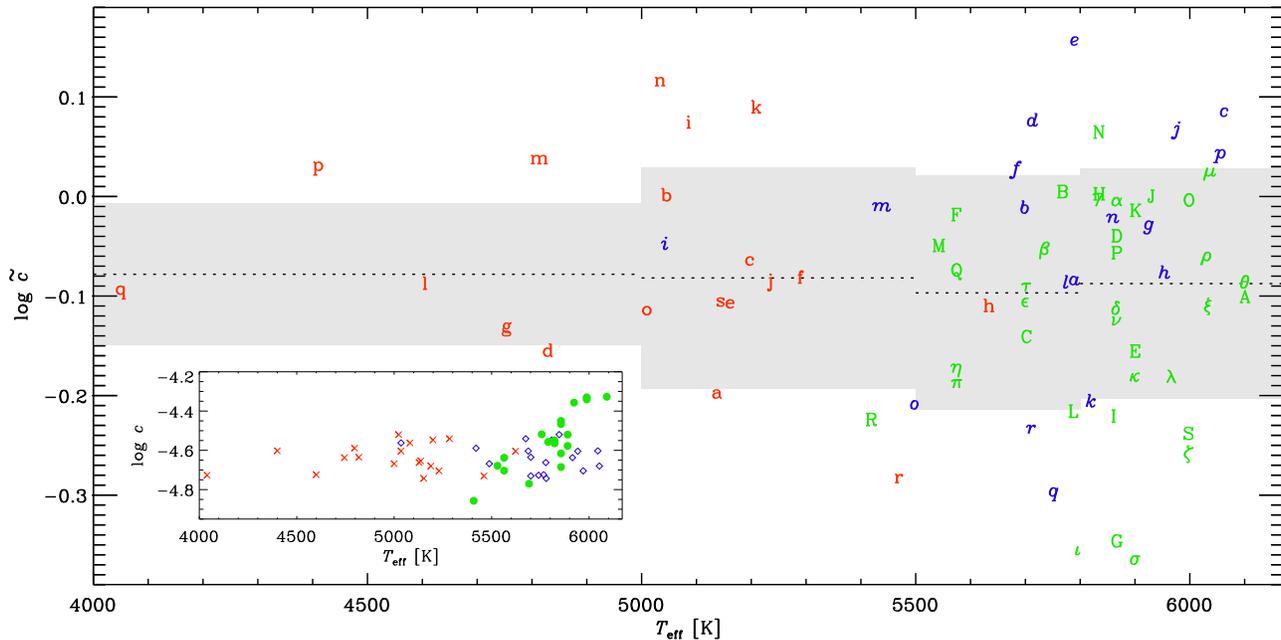

Figure 3. Dependence of the residual $\log \bar{c}$ on T_{eff} , which corresponds to the dotted lines in Figures 1 and 2. Again, some of the symbols have been shifted to avoid overlapping. Average and standard deviation are computed for smaller T_{eff} intervals, as indicated by horizontal dotted lines and gray boxes, respectively. The inset shows the residual $\log \bar{c}$ vs. T_{eff} .

to look at the usual residual $\log c = \log \langle R'_{\text{HK}} \rangle - \log(\tau/P_{\text{rot}})$, which was given in the inset of Figure 1 as a function of R'_{HK} and is now presented in the inset of Figure 3 as a function of T_{eff} . We see that the four hottest stars of the sample, S603 (green A), S1095 (green J), S1252 (green O), and S1420 (green S) have a slight, but systematic excess. Assuming that their values of R'_{HK} and P_{rot} are accurate, this could mean that the estimated values of τ are too small. Gilliland (1985) found that for a certain regime of evolution, stars of the solar mass and above may have τ significantly larger (up to 0.4 dex) than those of main-sequence stars at the same effective temperature (see their Figure 10). However, the regime for this behavior occurred only when these stars cooled to below the solar main-sequence effective temperature. As can be seen in the color–magnitude diagram in Giampapa et al. (2006), our sample does not include stars that have cooled to this degree; on the contrary, our sample is still very near the main sequence, and therefore we expect Equation (3) to still apply. This would therefore not alter our suggestion that most of the members of M67 have antisolar DR.

4. Conclusions

The phenomenon of antisolar DR is well known from theoretical models of solar/stellar convective dynamos in spherical shells. So far, antisolar DR has only been observed in some K giants (Strassmeier et al. 2003; Weber et al. 2005; Kóvári et al. 2015, 2017) and subgiants (Harutyunyan et al. 2016), but not yet in dwarfs. Our work is compatible with the interpretation that the enhanced activity at large Rossby numbers (slow rotation) is a manifestation of antisolar DR. Our results are suggestive of a bifurcation into two groups of stars: those that undergo reduced braking and become inactive at $P_{\text{rot}}/\tau \approx 2$ (van Saders et al. 2016), and those that enter the regime of antisolar rotation and continue to brake at enhanced activity, although with chaotic time variability. Interestingly, Katsova et al. (2018) have suggested that stars with antisolar DR may be prone to exhibiting superflares

(Maehara et al. 2012; Candelaresi et al. 2014). This would indeed be consistent with the anticipated chaotic time variability of such stars.

The available time series are too short to detect antisolar DR through changes in the apparent rotation rate that would be associated with spots at different latitudes; see Reinhold & Arlt (2015) for details of a new technique. It is therefore important to use future opportunities, possibly still with *Kepler*, to repeat those measurements at later times when the magnetic activity belts might have changed in position.

We thank the referee for thoughtful comments. We are indebted to Bengt Gustafsson and Travis Metcalfe for useful discussions and Dmitry Sokoloff for alerting us of their recent paper. This work has been supported in part by the NSF Astronomy and Astrophysics Grants Program (grant 1615100), the Research Council of Norway under the FRINATEK (grant 231444), and the University of Colorado through its support of the George Ellery Hale visiting faculty appointment. We gratefully acknowledge partial support of this investigation by grants to AURA/NSO from, respectively, the NASA *Kepler/K2* Guest Observer program through Agreement No. NNX15AV53G and from the NN-EXPLORE program through JPL RSA 1533727, which is administered by the NASA Exoplanet Science Institute (NExScI). The National Solar Observatory is operated by AURA under a cooperative agreement with the National Science Foundation.
